Kiel Working Paper No. 1812 | December 2012

Sustainable Agriculture and Food Security in Africa: An Overview

Linda Kleemann

Abstract

The development of the agricultural sector and the improvement of the food security situation are seen as essential components to sustainable development in Africa. However, continuing population growth, impacts of climate change and environmental degradation add to an unprecedented combination of pressures that threaten existing efforts and solutions. This article discusses the challenges of meeting the food security needs in a sustainable way. Due to its involvement of all three dimensions of sustainable development, economic, social and ecological, we argue that organic farming could be one possible approach to create a more sustainable agricultural system.

Keywords: sustainability, organic agriculture, food security

1 Introduction

It is widely accepted that hunger and malnutrition are not just a problem of food availability, but also a problem of access to food. As argued by Sen (1999), people suffer from hunger when they cannot establish their entitlement over an adequate amount of food. Thus, to eliminate hunger and malnutrition in the long-run, it is crucial to understand how policies can increase the production of food and ensure an equitable distribution of the food produced, as well as of the resources needed for production. Both policy makers and analysts acknowledge the need for improving agricultural productivity and in boosting food security in Africa. However, the problem of long-term food security appears to be compounded by the effects of climate change, large-scale investments in agricultural land, and highly volatile world market prices, especially for staple foods. Successively evolving causes and context factors, as well as multiple reciprocal cause-effect relationships complicate the ability to make a clear-cut statement of causality. The expansion of the world population, changing consumer habits, which lead to an increase in the demand for meat products, along with EU agricultural subsidies and the use of land for cultivation of biofuels, are just some of the many complex influential factors (von Braun et al., 2008).

The development of the agricultural sector and the improvement of the food security situation strongly influence other sectors of the economy and are seen as essential components to sustainable development in Africa. Progress in achieving food security is also a prerequisite to achieving the Millennium Development Goals (MDGs).¹ From the African perspective, the fight against hunger is the most pressing social challenge. On the production side, it is of dire importance to increase the productivity of smallholder farming and the more effective use of large farms to meet the dietary needs of the rural poor. At the same time, it is also necessary to reduce the environmental impacts of the agricultural sector so as to not destroy its own ecological foundations. In many parts of Africa, the land is already strongly degraded. The agricultural successes of the recent decades, with their methods of increasing productivity by use of mineral fertilizers and pesticides, have damaged the foundations of the long-term productivity of the land (IAASTD, 2009).

Globalization has also posed a second challenge to the African farming landscape. According to the IAASTD, the global demand for grain will increase by 75% from 2000 to 2050 (IAASTD, 2009). Hence, a dwindling amount of water and soil must feed more people, and, at the same time, feed animals for meat production as well as produce energy crops and biomass for the chemical industry. This raises the pressure on an already precarious food supply in Africa.

Due to the complexity of the influencing factors, the approaches to be pursued in order to achieve sustainable agriculture and food security in Africa need to be differentiated and tailored to the specific circumstances. Drawing on available literature, this article presents an overview of the challenges facing sustainable food production in sub-Saharan Africa. Given the potential conflict between increased food production that may lead to both higher emissions and better food security, information on the sustainability of food production in sub-Saharan Africa could be of interest to both analysts and policy makers.

The paper is structured as follows. The next section discusses the concept of sustainability, as well as the three dimensions of sustainability. This is followed by an outline of the food security challenges in sub-Saharan Africa and the reasons for the low agricultural productivity. The fourth section discusses the strategies employed to promote sustainable food production in the region. The final section presents concluding remarks and implications.

2 Sustainable Agriculture and Food Security

2.1 Sustainability in Agriculture

Development is defined as sustainable according to the so-called Brundtland report when it 'meets the needs of the present without compromising the ability of future generations to meet their own needs' (UN WCED, 1987). Sustainable agriculture and food security therefore stands for maximizing the productivity of the land and improving the well-being of people under the constraint of minimal damage to natural resources (land, water, air, and biodiversity) (Pretty, 1999). Agriculture is seen as a multifunctional system. Through the

incorporation of the whole value chain for food products, nutrition becomes part of this system.

Sustainable agriculture has often been discussed in a controversial manner, with various authors suggesting different competing strategies to accomplish this goal. Pretty (1999) uses a capital-based model of agriculture, in which capital consists of natural, social, human, financial and physical capital, and provides services that underpin the agricultural system. Capital in this model is affected by politics, production processes and institutions. If this influence is successfully used, feedback processes will strengthen the capital base. If it is not successfully used, then it results for instance in environmental pollution or social tensions, which reduce the total capital stock. According to Pretty, a sustainable system increases the capital stock over time. Other authors assume that an absence of capital stock reduction is sufficient. Availability of and access to the five different types of capital depends on contextual factors. These are divided, according to Pretty, into (short term) fixed factors (e.g. climate, agricultural ecology, soil and culture) and dynamic factors that can be externally influenced (e.g. legislation) (Pretty, 1999). The problem with models of this kind is the absence of a comparable measure for evaluating the different parts of the capital stock. Dimensions used to approximate such a measure are energy or monetary values.

In the three pillars of sustainability, economic sustainability ensures that farmers do not make any financial losses. This means, first, that his physical and financial capital, expressed in monetary units, does not decrease, which in turn is influenced by factors, such as prices, conditions of trade and yield that are considered in the following paragraphs in more detail.

The first factor, prices, often opens up the question of whether high food prices help to promote African farmers. This cannot be easily answered. The price fluctuations of the past four years and the resulting scientific studies do not show a clear picture. High prices can make farming in Africa more profitable and encourage investment in the sector. At the individual level, this is especially true for farmers who have enough land and access to adequate infrastructure, and are able to meet stringent international quality standards. Those

who should benefit under the social aspect of sustainability, namely small and poor farmers lose from increasing prices, because they are mostly net food buyers (see for example Swinnen, 2011, World Bank, 2008). In the long term, they could also benefit if high prices lead to increased investment in food production and thereby to a higher production volume that is shared equitably. However that part of the price increases and price volatility that can be traced back to speculation (Gilbert, 2010), affects all farmers negatively through increased uncertainty.

Second are conditions of trade. Small farmers in Africa have so far hardly benefited from the benefits of international agricultural trade because barriers are high between African countries and regulations for processed food in both developed countries hamper processing industries (IAASTD, 2009). Against the backdrop of growing markets for high quality and organic products in industrialized countries, new marketing channels are opening up. These can create new income opportunities under the condition that there is support for farmers to meet the required environmental regulations and quality standards.

Third, for economic sustainability with particular consideration to small farmers, framework conditions are particularly important. This concerns the physical infrastructure—especially transport routes, markets and storage facilities, the information infrastructure, and the institutional framework. Numerous studies emphasize the significance of contract security (for the reduction of transaction costs), and social safety nets (e.g. agricultural insurance) (Barrett et al., 2012). Also, land ownership or secure long-term leases are starting points to enable small farmers to escape out of poverty and malnutrition, since access to credit and investments in innovations and long-term measures, such as the preservation of soil fertility, are highly correlated to the security of land tenure (Abdulai, et al., 2011).

The social dimension of sustainability in agriculture and nutrition is reflected in the justice, health, distribution, gender, and cultural aspects of society and is summarized in Pretty's model under social and human capital. Without long-term food security social sustainability is inconceivable. Increases in global food production will only lead to the alleviation of hunger, when the availability of food for the poor, through lower prices, higher

incomes or better infrastructure, is improved. Measures to increase production volumes can even deteriorate access when vulnerable parts of the society are deprived of the opportunity for subsistence agriculture without simultaneously creating new income opportunities for them.

Against the backdrop of a growing global demand for resource-intensive food and renewable raw materials, a further intensification of agricultural production in Africa risks that its benefits are not used primarily to improve food security. 1 to 2% of global arable land is already used for energy crops and this number shows an upward trend. On social grounds, among the major causes of rural poverty and malnutrition are the unequal distribution of land and insecure and unclear land tenure rights. With the aim of counteracting unequal distribution of land, land reforms have been implemented in several African countries. However, not all have been successful. The ongoing relocation of peasants to make way for large-scale agricultural investment projects counteracts these efforts to distribute land more equally. In addition, from a social standpoint, access to water should be fairly distributed and the use of limited water resources should primarily benefit food security.

The improvement of educational opportunities for the poor is an effective way to create social sustainability while combating hunger. Numerous studies show a positive correlation between education level, income opportunities and nutritional status. A virtuous cycle is set in motion because well-fed and, thus healthier people are better able to feed themselves adequately and have improved employment opportunities. To this adds the advantage of better education for agricultural production itself, since sustainable agriculture is highly knowledge intensive.

The final pillar of sustainability concerns natural capital, which is termed ecological sustainability. It is based strongly on the original ideas of sustainability, not to overexploit nature. An ecologically sustainable way of life would use the environment and natural resources only to an extent that these regenerate. In particular, the industrial high-yielding agriculture is often viewed as environmentally unsustainable as it is very input-intensive and dominated by large-scale monocultures.

2.2 Is Africa's food security situation sustainable?

The food security and nutrition situation in sub-Saharan Africa is clearly not sustainable. Even though a recent report from the United Nations on the Millennium Development Goals discloses that the number of people living in absolute poverty in developing countries has declined from 1.8 billion in 1990 to 1.4 billion in 2005, the regional and intra-African distribution of poverty is highly heterogeneous: in Sub Saharan Africa- the world region with the highest poverty rate- 51% of the population lived in absolute poverty in 2005; in South Asia that number was at 39% of the population; in the Latin American-Caribbean region, 8%, and in Northern Africa it is at 3% of the population (UN, 2010).

Poverty can hinder the acquisition of sufficient quantities of food and affects both the urban and rural population. In the latter, poverty can prevent improvements in productivity when inputs cannot be purchased. Labor productivity is also low due to little educational opportunities and inadequate access to health care and/or malnutrition leading a vicious cycle of poverty and hunger.

While the proportion of hungry people in the world has declined recently, the absolute number has increased (according to data from FAOSTAT). According to statistics from the UNSCN, the southern Africa region with 239 million hungry people comes second after the Asia Pacific region with 578 million. However, the number of hungry people in Asia has decreased over the past 20 years while it has increased by 40% in Africa. In percentage terms Sub-Saharan Africa leads the way with 25% malnourishment. Accordingly, the World Hunger Index (WHI)² prepared by IFPRI, Concern Worldwide, and Welthungerhilfe (2011), also shows the worst picture for Southern Africa and the worst country case examples are also in Africa: Congo, Burundi, Eritrea and Chad, where continuing conflict and political instability worsen the situation.

Beyond the mere lack of calories, the problem of food insecurity also includes the so-called hidden hunger; that is malnutrition due to nutrient deficiencies, such as vitamin and mineral deficiencies. These are mostly associated with other health problems (von Braun, 2001)³. Again Africa is the largest region in the world with a high nutrient deficiency. On a

global scale, deficiencies in iodine affect an estimated two billion people worldwide, zinc (1.2 to 2 billion), iron (0.8 to 1.2 billion), and Vitamin A, that can cause blindness (200 million), are the most common. Many people suffer from multiple micronutrient deficiencies.

The problem of food security in Africa is as much a problem of quantity as a question of access. Taking the current world harvest as basis, there is theoretically more than sufficient energy available globally, namely the equivalent of about 800 grams of grain per day (Flachowski, 2011)⁴. Nonetheless, this amount is distributed extremely unequally. Africa imports far more food than it exports (Figure 2.1) and the quantity of imports has increased significantly over the last five decades, as per-capita food production has continuously declined (Mc Arthur, 2011). Inaccessible rural areas and areas of conflict are particularly underserved. The presence of adequate amount of food and nutrients is therefore a necessary but not a satisfactory condition for food security.

There are two types of access to food: self-sufficiency and markets. As a result of poverty, subsistence farmers are unable to feed themselves because they have insufficient factors of production at their disposal. Under these circumstances, they are just as dependent as the urban population on the purchase of food products. These parts of the population at risk of hunger or already food insecure are particularly vulnerable to changes in food markets. The most obvious example is rising prices. The average African spends 50-80% of his income on food, compared to 12% for the average German. Under these circumstances, rising food prices lead to reduced intake of calories and/or a reduction in the quality and diversity of food. Often animal products, fruits and vegetables are replaced by cheaper grains (UNSCN, 2010). Table A.2.1 shows the enormous differences in caloric intake and consumption of food of animal origin. It is noteworthy to mention that the minimum in all the above mentioned categories is in Africa.

Some African countries suffer from the so-called 'double burden of hunger and obesity', i.e. the simultaneous problem of malnutrition and obesity and the resulting health issues. The background behind this problem lies with the adaption to the dietary habits and

eating styles of the industrialized countries - the so-called 'nutrition transition' (Mendez and Popkin, 2004).

3 Reasons for the Current Agriculture and Food Security Situation in Africa

The relationship between the three pillars of sustainability is particularly obvious in agriculture. If the soil is degraded, farming will not be economically productive. That is, it produces too little food. As a result, people suffer from hunger or malnutrition, which in turn leads to a destruction of natural resources. This implies that ecological sustainability is influenced not only by geographic and climatic factors and changes in agricultural technologies, but rather depends more on political, social and economic terms. These factors are discussed in this section.

Starting with geographical conditions, a large part of Africa's climate is considered not well suited for agriculture, a reason often given for its long history of famines. This is expressed as a limited availability of natural resources, especially water, even though Africa is rich in many other natural resources.

For instance land is not generally considered a limiting factor for the African agricultural landscape. Large stretches of land have so far hardly been put into agricultural use. However, only 10% of the land is truly fertile (UNEP, 2008a) and 13- 16% of the arable land has been damaged from erosion or been degraded as a result of other chemical and physical changes, such as infrastructure, cities, and pollutants (Bai et al., 2008). A recent study by von Braun et al. (2011) shows that about 17% of the agricultural production in Sub-Saharan Africa is lost due to land degradation, in some regions up to 40%, and on average 8% throughout the continent. In This consequently leads to an increasing use of moderately arable soils. Forests, which cover about 20% of the African landscape, are strongly deforested. The deforestation rate is more than four million hectares per year, twice the world average (Kelatwang and Garzuglia, 2006).

Rapid population growth raises the pressure on the forests and already heavily farmed areas. Almost the entire global population growth in the next couple of years will,

according to calculations done by the United Nations, take place in developing countries. This will increase the populations in many African countries by more than 50%. Through this population surge, the amount of theoretically available arable land per person is predicted to decline from 4.7 hectares per person in 1970 to 1.5 in 2050. In reality, this may occur faster than predicted in the model, since competition from renewable resources and settlements must be considered in the equation. Due to the fact that settlements are often located in fertile river valleys and coastal plains, some of the best agricultural land is converted almost irreversibly into cities and roads.

Africa is the warmest and second-driest continent, making water a limiting factor in the expansion of the agricultural landscape. Water is as much a staple food as a basis for food production. With an average share of 70%, in some African countries even above 90% agriculture uses the most amount of water. This water use is not sustainable if the rate of use exceeds ground water recharge or if it leads to a contamination of ground- or surface water. According to the Intergovernmental Panel on Climate Change (IPCC) irregular and reduced precipitation will quadruple the number of people affected by water shortages in Africa by the year 2050 to more than 250 million (IPCC, 2007). Low levels of irrigation in agriculture and efficiency in water use limit agricultural production growth.

The effects of global warming are already appear to be destroying harvests and threatening food security in Africa. There are five major effects of climate change on agriculture: First, the increases in the concentration of CO₂ in the atmosphere, which can in turn lead to a fertilization effect; second, higher average temperatures and third, changes in the availability of water, which are expected to have strong yet different regional effects. Fourth is the increased weather extremes and fifth, higher soil degradation that can lead to significant harvest losses (Dusseldorp and Sauter, 2011). The expected rise in droughts for already dry regions and the higher risk of flooding wetlands will present Africa with higher risks for famine. Globally, the entire agricultural yield potential is not expected to change significantly by 2080 due to the effects of climate change, yet predictions for Africa are negative. By 2020, crop yields from rain-fed agriculture, which accounts for 90% of farming,

in some African countries are projected to decline by up to 50% (IPCC, 2007). The United Nations Environment Program reports that the total of climate-related decline in agricultural production will be as much as 10% in southern Africa (UNEP, 2008a).

Further reducing local availability of food post-harvest losses amount to about one-third of the total harvest volume.⁵ In southern and eastern Africa, the post-harvest losses in cereals alone are 10-30%. In Tanzania, about 60 million liters of milk (16% of the total production in the dry season and 25% in the rainy season) are lost (UNSCN, 2010). Large post-harvest losses are caused by lack of investment in harvesting technology and storage facilities, improper handling and transport, and poor infrastructure. Even in densely populated areas in parts of Southern Africa it may take more than five hours to reach the nearest market (Nellemann et al, 2009). Much of the post-harvest losses could be prevented with existing technology if invested locally, but weak institutions and political instability in some countries discourage investments.

Another key factor that contributes to a decline in agricultural productivity is low spending on research and development (R&D) in agriculture. While other developing countries recorded an increasing trend, the real expenditure on agricultural R&D in southern Africa has been decreasing. In 1981, the expenditures were at US\$1.15 billion; in 2000 they decreased to US\$0.87 billion (UNEP, 2008b). In addition, protected agricultural markets reduce profits in the sector and thereby limit investments. Rosegrant et al. (2001) calculate that global trade liberalization in the agricultural sector would allow for an estimated US\$4.4 billion in additional income in sub-Saharan Africa (US\$22 billion for all developing countries). However, depending on comparative advantages, a strategy of export growth within a weak national regulatory framework can negatively affect ecological sustainability.

On the demand side the weak purchasing power of the African populations slows down progress. Poverty not only causes low demand, it also increases environmental degradation. Bai et al. (2008) find a positive correlation between the degradation of land and poverty. This relationship is explained by the attempt of the resource poor to be self-sufficient, without concerns for the environment. At the same time environmental degradation

is taking away the most important resource from the poor and thereby reinforces their poverty, producing a vicious circle.

The climatic and economic factors mentioned combined with the low prices for land in Africa, make farmland attractive to investors. Financially strong state and private investors have recently been either long-term leasing or purchasing large areas of productive farmland. The economic, ecological and social consequences of such investments are controversial. On the one hand, the agricultural policy in Africa has been neglected so that there is a strong need for investment. On the other hand, there is not only an unstable food security situation, but also unclear property rights and weak government control and regulation in many African countries. Contracts for land can thereby place both the local population and the environment at a disadvantage. Unregulated land use can either lead to degradation and erosion, high greenhouse gas emissions, and overuse of the water supply or take advantage of unexploited harvest potentials, and an increase productivity and food security. The local population may lose their land without adequate compensation or they may profit from better infrastructure and new employment possibilities in rural areas.

Against the background of climate change, agriculture also plays an important role in ecological sustainability. About one-third of all global greenhouse gas emissions come from farming (UNEP, 2008a), where the emissions from the livestock industry are in the most critical position since it claims 70% of agricultural land in the world (IAASTD, 2009). A meat-based diet affects the ecological sustainability negatively, because the direct emissions (through the livestock themselves) and the indirect emissions (through fodder production) are on average higher than for the production of plant-based foods, though, the emission level depends, among other things, on the technology used and the location of production. Figure 2.2 shows the nitrogen oxide emissions for different world regions. Africa has the lowest amount of emissions. However, agriculture has a far bigger share in this region than in richer regions of the world⁶.

Environmental degradation is a major limiting factor of agricultural productivity growth. When soils are subject to unsustainable exploitation in the course of food production, these

processes limit their suitability for or impede further use (through erosion, salinization, acidification, compaction, contamination with toxic substances and the loss of soil organic matter). A sustainable agriculture must at least maintain, and best promote soil fertility. Since agricultural use generally leads to a net discharge of nutrients from the soil, they have to be replaced through organic or mineral fertilizers. The protection of soil fertility requires a long-term investment. Unclear and weak property rights in land reduce incentives to invest in the resource land, and to take measures to improve the soil and prevent erosion (e.g. Abdulai et al., 2010). Investments in land in turn affect farming yields, which are higher for users with secure land rights than for users with insecure land rights.

Climate change and agriculture share a reciprocal relationship: on the one hand, agriculture influences climate change in several ways; on the other hand, climate change affects agricultural production. Changes in rainfall, temperature and other climatic factors are expected to negatively affect food production in Africa (see section 2).

This overview shows that there are many, partly competing aspects of sustainability. Proposed solutions aim to cover one or more aspects more or less completely.

4 Solution Proposals and the Example of Organic Farming

4.1 Solution Proposals

There are a number of partly competing proposals that prioritize different aspects of sustainability differently. The question of the best priorities and solutions is highly controversial.

As traditionally most poor work in farming, many researchers believe that growth in the agricultural sector is the most effective way to reduce poverty and thereby increase food security (e.g. Dewbre et al., 2011, Byerlee et al., 2009, Thirtle et al., 2003). But whether this is done best by the establishment of large farms or supporting existing smallholders is a critical point of disagreement between scientists.

The Alliance for a Green Revolution for Africa promotes a package of new high-yielding varieties, increased use of inputs and better access to markets and financial

services. Whether or not genetic engineering of crops should be part of such a strategy is subject to intense debate. Amid the potential benefits are high-yielding crops that grow under adverse environmental conditions and on so far unsuitable lands. Opponents point towards the risks of reducing genetic diversity and contamination of the natural environment.

Adaptation to climate change is also needed, using better technology or expanding cultivated land or compensate through increasing food imports. This solution would target the use of plants that can adapt to new climate conditions and the adjustment of agricultural methods, such as the timing of sowing and the use of water. Additionally, agroforestry has the potential to mitigate the effects of climate change (IAASTD, 2009).

Among the less contested proposals for ways forward is a strong increase in agricultural research, education and extension services. The CAADP (Comprehensive Africa Agriculture Development Program) under the supervision of the African Union agreed on a target mark of 1% of the income in agriculture to be spent for agricultural research as well as 10% of the total government budget that should be put into agriculture in general. Most of the participating countries do not achieve these targets yet, but there is a positive development (Omilola et al., 2010). Industrialized countries could also invest more in research, in particular to reduce the latent conflict between environmental protection, resource conservation and food security. Estimates by IFPRI suggest that 20-30% of global development assistance should be channeled into agriculture to ensure food security (vbn Braun et al., 2008). Furthermore, a reduction of trade restrictions by developed countries and a decrease in subsidies for the domestic agricultural industry would be beneficial for the agricultural sector in Africa in general.

Now, one solution proposal, organic agriculture, will be discussed in more detail and with special attention to local circumstances and alternatives in Africa. As the name suggests, it is aimed at principally ecological sustainability. The central theme of organic farming is conducting economic activity in accordance with the principles of ecosystems. This allegedly leads to improved (social, ecological and economic) sustainability (Lampkin and Padel, 1994). Besides the production of food, raw materials or energy, agriculture is

responsible for environmental and resource protection. Instead of relying on the principle of output maximization, as used in conventional agriculture, inputs are optimized. Nutrients should be efficiently used in quasi-closed cycles. These principles lead to a focus on the use of local resources and the avoidance of external inputs where possible. Organic farming also seeks to increase productivity but only as long as intensification of production is compatible with sustainability.

In Africa, organic farming is often promoted as a promising sustainability and food security strategy. Due to its similarity to the traditional local agriculture, the transition to organic farming is supposed to be particularly easy to achieve for poor farmers that live in remote areas. Additionally, converting to organic farming supposedly eliminates the dependence on expensive fertilizers and pesticides. Whereas uncertified produce usually serves the local market, certified organic produce in Africa is almost exclusively allocated to the export market. Europe and North America account for 97% of the world market (Willer and Kilcher, 2009), and the market is growing rapidly in these regions. Many studies have demonstrated the willingness of consumers to pay a higher price for organic products (e.g. Bjorner et al., 2004; Loureiro and Hine, 2002; Nimon and Beghin, 1999). Hence, certified organic produce also offers an attractive market in the North. This is why in Africa most organic produce is certified according EU or US organic regulations. So far, there has been little research into the demand for organic - certified or uncertified - produce within Africa.

When limited resources such as phosphate and the rising costs of energy-intensive production of mineral fertilizers lead to increases in production costs and farmers in marginal areas of Africa face already high costs due to poor infrastructure, the substitution of artificial fertilizers with organic compost can be not only an ecological, but also an economic advantage. Therefore conversion to organic agriculture in Africa is promoted by a range of non-governmental organizations, development cooperation projects and entrepreneurial initiatives.

4.2 Economic Impacts of Organic Agriculture

The yield potential of organic farming in locations with medium and low soil productivity, especially in the tropics and subtropics, is perceived to be equal or superior to that of conventional production at the present state of knowledge. This is due to the fact that inputs used in conventional farming are often used in low quantities or not at all by farmers in these regions that the effectiveness of mineral fertilizers on soils with low nutrient retention capacity is reduced, and that high-yielding varieties are often unsuitable for cultivation in sub-optimal locations. According to Dusseldorp and Sauter (2011), the great variance in results in empirical studies comparing yields from conventional and organic production indicates that the potential for intensifying ecological production is underutilized in comparison to conventional production and that widespread view that organic farming could only feed a small proportion of the world's population is a preliminary judgment based on limited data.

A number of scientific studies have employed case studies to examine the economic consequences of a conversion to organic farming and organic certification for small farmers in developing countries. Even if, due to the methodology employed in the studies, it is not always clear whether the results stem from the actual conversion, or from other aspects, e.g. unobservable characteristics of the farmers, generally a cautious positive image emerges from the results. A study by Pretty and Hine (2001) that observes a group of 208 sustainable agriculture projects in Africa, Asia and Latin America, shows that sustainable agriculture can increase yields and visibly improves the overall nutritional condition of small farmers. In the 45 projects examined in 17 African countries, the production volume of the farms increased in all cases. Also, according to Pretty (1999), natural and human capital, which are the basis for the sustainability of projects, were accumulated. Overall, most studies find that because of higher prices from certified organic products, small farmers profit more from certified organic, than from conventional farming, while production costs are similar to those of conventional production⁷ (e.g. Bolwig et al., 2009; Maertens and Swinnen, 2009). Hence, those farmers that manage to meet the certification requirements and quality standards of the international market are most likely to benefit.

The question of whether and under what circumstances a significant number of farmers are able to meet these standards, has a mixed answer. The literature gives us both positive and negative examples (e.g. Markelova et.al, 2009; Roy and Thorat, 2008; Wollni and Zellner, 2007). The cost of certification alone is generally not affordable for small farmers or cooperatives in Africa without substantial support by governments, businesses or aid programs.⁸

Furthermore, the high level of management and knowledge intensity of organic farming can be an important entry barrier for poorly educated farmers with limited access to information systems and poor links to other farmers in similar situations and is often a reason for the breakdown of organic agriculture initiatives in Africa. This problem is also reflected in the low yields that are reported in many scientific studies on organic compared to conventional small-scale farms in Africa despite the aforementioned yield potentials.

Organic and sustainable agriculture are often equated colloquially. However, several tests have shown that organic agriculture plus minor use of chemical inputs often reach the best results in terms of yield and environmental compatibility in an African context, and thus could be called sustainable, too. However, in this case the option of certification and thereby to achieve higher prices is no longer applicable.

4.3 Social Impacts of Organic Agriculture

With respect to the improvement of the nutritional situation of the disadvantaged and rural population that are mainly peasant farmers, it seems that organic agriculture can empower them to increase their production with limited productive resources, to decrease their production risk by enhancing the diversity of their cultivation systems and therefore to contribute to adapting to climate change. Furthermore, higher labor intensity and lower capital intensity of organic agriculture can have a positive impact on employment opportunities in rural areas. Studies have shown that by refraining from using chemicals, which were rarely used properly, a positive impact on the health of farmers (fewer symptoms

of poisoning, less water-related health issues) could be observed. So far, however, in most cases not all of the named potentials are being exploited.

Cultural proximity to traditional agriculture is often highlighted by supporters. However, this aspect is hard to investigate empirically. Nevertheless, it seems that organic agriculture is more suitable for (traditional) small and medium-scale diversified farms and less for (modern) large-scale specialized plantations. If this tendency is confirmed, the poorer parts of the rural population, respectively small-scale farmers, could benefit disproportionately from investments in the sector. If the yield potential of organic agriculture would be utilized, the availability of food would increase where access to food is the limiting factor for food security. Likewise, the above mentioned support of small-scale farmers with new production technologies, and the distribution of agricultural knowledge and training act in a similar fashion as investments in education of the rural population.

4.4 Ecological Impacts of Organic Agriculture

Obviously, abstaining from the use of chemical additives has a positive impact on the environment through lower pollution. This positive aspect is particularly important in Africa, because improper use of chemicals in agriculture by African small-scale farmers is very common, including the use of excessive amounts, insufficient safety measures during application, careless storage and use of highly toxic outdated substances.

Since agricultural use leads to a net outflow of nutrients from the soil, especially when crop production and livestock are spatially separated, nutrients have to be supplied through organic or mineral fertilizer to preserve soil fertility and thus the yield potential of the soil. Small-scale farmers in developing countries often fail in doing so. There is a tendency that farmers which are getting certified are those who practice so-called 'organic by default' agriculture, i.e. traditional shifting cultivation without or with low addition of nutrients. From an ecological point of view, this method will only be sustainable if the fallow period is long enough, which is rarely anymore the case due to an increasing population density and resulting shortage of land. In the present circumstances, this method leads to leaching of

soils. So far no scientific studies exist that can affirm or reject this hypothesis on the basis of data on the nutrient content of agricultural soils. However, there are many studies, including those named in the last section that suggest that the principles of organic agriculture are understood and taught as negative laws in Africa. Little importance is given to positive instructions, of what one should do to maintain soil fertility. In this respect, organic farming in Africa has a vast untapped potential. This type of agriculture can have positive effects on the protection of resources, of the soil and the biodiversity if the application of the principle of the closed nutrient cycle is applied. A number of studies (such as Niggli and Kasterine, 2007 and UNCTAD, 2006) have also shown that organic agriculture does better than conventional agriculture in adaptation to and prevention of climate change. Through a better CO₂-balance, organic farming can mitigate the effects of climate change. The amount of emissions per hectare is significantly lower; however they are similar or higher per unit of output. In addition, organically managed soils absorb more CO₂ (carbon sequestration) (Niggli and Kasterine, 2007). Furthermore, adapting to climate change seems easier using organic farming because the induced diversification spreads risk and more robust varieties are grown (UNCTAD, 2006; Stolze et al., 2000).

Some authors conclude that practicing organic farming in conformity with its holistic principles leads to synergies that only come through the interplay of several factors (e.g., Pretty, 1999; Shiferaw and Holden, 1999). The change of single factors– a *ceteris paribus* approach –, for example the introduction of water conservation practices through terraces without making improvements at other points of the system at the same time is much more ineffective and possibly unprofitable than if several factors are changed together. In this example this could be the further simultaneous use of improved organic fertilizer to increase productivity and the improvement of access to the credit market to finance the new activities.

4.5 Adoption and Diffusion of Organic Agriculture

The number of certified small-scale farmers is relatively high. In 2009, Uganda was, after India, the country with the second largest number of certified producers in the world, and

Ethiopia, Tanzania and Burkina Faso were also ranked in to the top ten (Willer and Kilcher, 2009). However organic-certified agricultural land in Africa remains limited despite intensive research and mostly positive observed impacts and untapped potentials of organic agriculture (see Figure 2.3).

There is a vast literature on the adoption and diffusion of agricultural technologies in developing countries (see e.g. Feder et al., 1985 and Feder and Savastano, 2006; Foster and Rosenzweig, 1995, 1996, and 2010) trying to explain this phenomenon. Scientific studies have identified several typical barriers to agricultural technology adoption which can be summarized in six groups: biophysical characteristics of farms, complexity of the technology, household features, poverty of the land tenants, property rights, and input and output markets. The width of this list shows that the spread of organic agriculture can stagnate at many points. The complexity of organic agriculture that exists due to its holistic approach is one of the reasons why its realization can be difficult or at least lengthy. A lot of support programs and initiatives just take up single aspects such as the certification. They also often do not accompany the whole process of conversion⁹. If the parts are interdependent, this strategy is not very helpful.

The time-lag of organic agriculture is a disadvantage. Many of the positive effects only become visible in the long-term, amongst others because soil fertility changes slowly. In the certification system this reflects in the three-year transitional period before products can be sold as organic certified.

Furthermore there are other aspects that can have a great impact on the diffusion of organic agriculture in Africa. One of these aspects is the role of collective institutions such as cooperatives which are frequently used to disseminate agricultural technologies and organize the process of certification for small-scale farmers. The meaning of the functioning of these institutions and the incentives for farmers to join them should not be underestimated. The investigation of the question how farmers or farm households decide for or against a new technology such as organic agriculture within a complex entity of new and old technologies, institutional environment, market conditions, available resources, and cultural and social

networks, cannot be derived from traditional theoretical models of agricultural household (e.g. de Janvry, et al., 1991) and is subject of current research. For instance, higher prices for final goods can have very diverse impacts. The return of land and labor increase and thereby encourage investments in agriculture. This can be new technologies that improve soil fertility. But higher prices can also cause the opposite and aggravate ecological damage. If these prices are not expected to be non-permanent, or the discount rate in the future is very high, it may make more sense for the farmer to leach the soil in order to make a higher profit quickly rather than investing in more sustainable long-term technologies.

Overall, the problem of slow diffusion is not just a problem of organic agriculture but many technologies in Africa and other developing countries. Therefore, a number of researchers currently try to answer questions about barriers to adoption and diffusion, and the question of individual profitability of new technologies (e.g. Suri, 2011).

5 Concluding Remarks

The increase in the number of both undernourished and malnourished people in sub-Saharan Africa over the last decade has intensified the calls for measures to help boost agricultural productivity and output in order to enhance the food security situation in the region. The challenge for African agriculture is therefore substantial. Alongside this challenge to find ways to increase food and livestock production are concerns about agricultural sustainability, as an unprecedented combination of pressures are emerging to threaten the sustainability of existing social and ecological systems. The continuing population growth, impacts of climate change and environmental degradation that are driving the limited resources towards their thresholds need to be taken into consideration in the development of sustainable production techniques.

This article discusses the challenges of meeting the food security needs in a sustainable way. Given that sustainable development is a concept that includes economic, social and ecological dimensions of conservation, we argue that the dual goals of ensuring food security and promoting sustainable production are achievable in the African context only

with the right policy mix. We use organic farming as one example for a sustainable development strategy for African agriculture and nutrition. Its big advantage is its involvement of all three sustainability criteria, but due to its complexity it has weaknesses, especially in implementation.

The study by Pretty and Hine (2001) which analyzed some projects involved in sustainable intensification showed that, provided there is a political and economic domestic recognition that agriculture matters, then food production can be increased without doing harm to the environment and increasing the flow of beneficial environmental services. In principle, organic farming is one possible approach to create a more sustainable agriculture. However, further studies on individual motifs and conditions of transition to organic farming are necessary. Under certain circumstances agricultural productivity can also be improved by organic farming, but more intensive and context-specific research to better utilization of its productive potential is needed.

On the market of ideas organic agriculture has to stand up to other strategies for action that promote their sustainability and come with other advantages and disadvantages. In a given political and institutional situation various strategies appear attractive in different ways. However, there are general principles that we consider important to recognize when selecting between alternatives. First, no strategy should work against food security, that is, the sufficient production of and access to food. Second, natural resources, a clean environment, human health and social justice are basic aspects for a functioning agriculture as well as for social and ecological sustainability. In the past, the development of the agriculture often focused singularly on increasing productivity. Third, future strategies have to acknowledge the multifunctionality of agriculture and take into account the complexity of agricultural systems within different socio-economic and ecological situations. Farmers are not just producers but also managers of ecosystems. The incentive systems for all actors in the agricultural sector and for consumers have to be changed in a way that they address this multifunctionality. In the sense of social sustainability, activities have to be geared more towards previously disadvantaged social strata such as farmers with limited resources.

To choose the right strategy mix, all possible economic, social and ecological consequences should be evaluated and used as basis for decisions. The weighting of individual advantages and disadvantages is necessarily a subjective one and depends on the institutional, political, societal and natural context.

Notes

¹ The MDGs consist of eight goals, each with one or more sub goals that have been established in 2000 by several international organizations to be achieved by 2015. MDG 1 stands for the halving of extreme poverty and hunger, MDG 7 concerns ecological sustainability, MDGs 4, 5 and 6, infant mortality rate, maternal mortality and the combating of major diseases, such as AIDS and malaria.

² The WHI is based on three values: the proportion of undernourished in the population, the proportion of underweight children under five years old and the mortality rate among children under five years of age.

³ **Food security** is defined as a state where an individual has at any time physical, social and economic access to sufficient, affordable, safe and nutritious food. **Undernourishment** is an aspect of food security measured as a state where the human intake of energy from food is below the minimum energy requirement of the body. This requirement is defined by the amount of energy necessary to achieve an acceptable size by weight ratio ("weight for attained height") and perform light physical activity.

Malnutrition is a broad term that includes all forms of malnutrition. It can have many different causes, including infections, and nutritional, and socio-cultural factors. Malnourishment encompasses both the concepts of undernourishment and of obesity (definition from the UNSCN, 2010).

⁴ The quantity of food needed to achieve individual food security, the number of humans and their average dietary energy requirements can be used to determine the total amount of food needed.

⁵ The estimates can be found for instance on the website www.phlosses.net

⁶ Nitrogen compounds generate the environmentally harmful substances ammoniac, nitrate and laughing gas (nitrous oxide).

⁷ Other sustainability standards like fair trade also yield positive results.

⁸ This is true for the export market in general due to its strict requirements. In addition, certifications such as GLOBALGAP for conventional produce are almost universally in demand in the export of fresh agricultural produce from Africa. For example, 76% of all fruits and vegetables in the European market are GLOBALGAP certified (PIP, 2009).

⁹ Even compensation payments that are regularly used in Latin America for carbon sinks have made little difference. Problems with the correct measurement of environmental services by agriculture add to the difficulties.
