Technological Regimes, Schumpeterian Patterns of Innovation and Firm Level Productivity Growth

Fulvio Castellacci and Jinghai Zheng

Department of International Economics,
Norwegian Institute of International Affairs (NUPI), Oslo, Norway

[Abstract] The paper investigates the relationships between technological regimes and firm-level productivity performance, and it explores how such a relationship differs in different Schumpeterian patterns of innovation. The analysis makes use of a rich dataset containing data on innovation and other economic characteristics of a large representative sample of Norwegian firms in manufacturing and service industries for the period 1998-2004. First, we decompose TFP growth into technical progress and efficiency changes by means of data envelopment analysis. We then estimate an empirical model that relates these two productivity components to the characteristics of technological regimes and a set of other firm-specific factors. The results indicate that: (1) TFP growth has mainly been achieved through technical progress, while technical efficiency has on average decreased; (2) the characteristics of technological regimes are important determinants of firm-level productivity growth, but their impacts on technical progress are different from the effects on efficiency change; (3) the estimated model works differently in the two Schumpeterian regimes. Technical progress has been more dynamic in Schumpeter Mark II industries, while efficiency change has been more important in Schumpeter Mark I markets.

Keywords: TFP growth; technical progress; technical efficiency; technological regimes; Schumpeterian patterns of innovation; CIS data

Acknowledgments: The paper has been presented at the ICONS Workshop in Oslo, November 2007, and at the FIG Workshop in Lund, January 2008. We wish to thank Per Botolf Maurseth and Svein Olav Nås for helpful comments and suggestions.

1. Introduction

The empirical literature studying the relationships between innovation and the productivity performance of firms represents by now a huge and important body of applied research. The field has recently experienced a surge of interest due to the increased availability of firm-level data for a large number of countries.

Some of these firm-level datasets, such as those from the *Community Innovation Survey* (CIS) in Europe, contain a rich variety of information on the innovative activities and strategies of thousands of enterprises, making it possible to significantly refine the measurement of inputs and outputs of the innovative process, as well as to include a variety of other related factors.

Recent microeconomic studies on the innovation-productivity link have increasingly made use of innovation survey data, and provided fresh empirical evidence on the relationships between innovation input and output, on the one hand, and between output and productivity, on the other (Crepon et al., 1998; Hall and Mairesse, 2006).

In our view, a crucial proposition that may be useful to refine this type of empirical approach is that the relationship between innovation and productivity may have a well distinct nature in different types of markets and industrial sectors. In order to refine our understanding of the innovation-productivity link, we need a theoretical approach that takes into account the sector-specific nature of technological change (Nelson and Winter, 1982; Malerba, 2002).

The general idea we put forward is that, given that firms in different industries of the economy face a distinct set of opportunities, constraints and conditions, these industry-specific characteristics play an important role to explain the enterprises' technological and productivity performance. In particular, in line with the recent work of Castellacci (2007), we argue that firm-level productivity growth is related to the characteristics that define the technological regime in which the enterprise operates.

More specifically, we explore the idea that the sources and mechanisms of productivity growth may be distinct in different types of sectoral market structure and industrial dynamics conditions. In a Schumpeter Mark II regime, the oligopolistic and concentrated nature of the market may make large incumbent innovators the dominant carriers of productivity growth. In contrast, the dynamics of productivity in a Schumpeter Mark I pattern may be led by an intense and turbulent process of compe-

tition where new innovators are more productive than the exit firms they replace (Foster et al., 1998).

In exploring this main idea, it is crucial to distinguish and measure different sources of productivity growth. We make use of frontier production function methods (data envelopment analysis) to decompose the growth of total factor productivity (TFP) into two distinct components, namely *technical progress* and *technical efficiency* (Färe et al. 1994; Zheng et al., 2003). The former is associated with changes in the best-practice production frontier, whereas the latter with other productivity changes, such as learning by doing, improved managerial practices, and change in the efficiency with which an existing technology is applied.

After having identified and measured these two distinct components of TFP growth, we will investigate (1) the role of technological regime-related factors to explain their dynamics, and (2) how the relationship between technological regimes, technical progress and efficiency change differs in the two Schumpeterian patterns of innovation.

The econometric study makes use of firm-level data for the Norwegian economy. The rich dataset we make use of combines together information from three different sources. Data for the estimation and decomposition of TFP are taken from a time series database that provides information on several thousands of Norwegian enterprises for the period 1998-2004. Data on innovative activities are from the *Third* and the *Fourth Community Innovation Survey* for Norway, referring to the 1998-2000 (CIS3) and 2002-2004 (CIS4) periods respectively. These three data sources all provide information on a very large and representative sample of Norwegian enterprises in manufacturing and service industries.

The paper follows this outline. Section 2 briefly reviews the empirical literature that provides the background and foundation for our study. Section 3 puts forward our theoretical model and main hypotheses. Section 4 presents the results of an econometric estimation of TFP growth, which identifies the separate contribution of technical progress and efficiency changes to the overall productivity dynamics of Norwegian firms. Section 5 shifts the focus to the determinants of these two components, and estimates an empirical model that tries to explain them by means of a set of variables measuring technological regimes and other firm-specific characteristics. Section 6 summarizes the results and concludes the paper.

2. The literature on innovation and firm-level productivity growth

In recent years, thanks to the increased availability and diffusion of large enterprise datasets, there has been a surge of interest in the measurement of productivity growth and the study of its determinants at the firm level (Caves, 1998; Foster et al., 1998; Bartelsman and Doms, 2000).

The measurement of firms' productivity has for a long time been an engaging field of applied research within industrial economics, which has produced a variety of models and techniques to estimate TFP and its dynamics (Heshmati, 2003). One interesting approach, in particular, has made use of frontier production function methods (e.g. data envelopment analysis) to decompose the growth of TFP into two distinct components, namely *technical progress* and *technical efficiency* (Nishimizu and Page, 1982; Färe et al. 1994). Technical progress is associated with changes in the best-practice production frontier, whereas technical efficiency growth is related to other types of productivity change, such as learning by doing, improved managerial practices, and change in the efficiency with which an existing technology is applied.

Besides decomposing the dynamics of TFP, this empirical literature has investigated the determinants of these two distinct components, and tried to relate them to a variety of characteristics of the firms and of the institutional and market conditions in which they operate (e.g. Zheng et al., 1998; Zheng et al., 2003).

To the best of our knowledge, though, this type of studies has not analysed the relationships between the innovative activities and strategies of enterprises, on the one hand, and their performance in terms of technical progress and technical efficiency. Does innovation increase productivity growth by pushing the technological frontier further (technical progress), or by improving the efficiency with which existing techniques are applied (efficiency change), or both? This interesting question, still unexplored in the literature, motivates our study.

In approaching this research issue, the large empirical literature studying the relationship between innovation and productivity growth provides us with a set of important insights and well-established results, which are useful to give a more solid foundation to our study. Applied studies on the impact of R&D activities on the dynamics of productivity represent by now a huge and important body of empirical research. The standard approach is to investigate the empirical relationship between the growth of

total factor productivity, on the one hand, and R&D expenditures and R&D spillovers, on the other (Griliches, 1979; Wieser, 2005).

Two recent developments in the innovation-productivity literature have particularly attracted the attention of scholars in the last few years. The first is the greater availability of innovation enterprise-level data for a large number of countries. Some of these firm-level datasets, such as those from the *Community Innovation Survey* (CIS) in Europe, contain a rich variety of information on the innovative activities and strategies of thousands of enterprises, making it possible to significantly refine the measurement of inputs and outputs of the innovative process and to include a variety of other related factors.

A second interesting development has been the progressive refinement of the traditional R&D productivity model. The current mainstream approach analyses innovation survey data by making use of the so-called CDM model (named after the authors of the seminal paper in this tradition, Crepon, Duguet and Mairesse, 1998). The CDM empirical model emphasizes the distinction between inputs and outputs of the innovative process, and points out that it is the innovative output that affects the productivity performance of firms, rather than their R&D activities (inputs) as commonly assumed by previous works.

This CDM type of studies typically estimates three equations: one for the determinants of innovation inputs (e.g. measured by total innovation intensity), one for the link between innovation input and output (measured by turnover from new products), and one for the impact of innovation output on productivity (labour productivity or TFP).

Besides the conceptual distinction between these different stages of the innovative process, another important contribution of this approach is the consideration of the possible problems created by the existence of sample selection bias in the context of firm-level data from innovation surveys. This problem typically arises because many of the questions on innovation strategies and activities in the CIS survey are only answered by firms that are innovative, whereas non-innovative enterprises skip those parts of the questionnaire that are not relevant for them. CDM econometric models control for and correct this type of selection-bias (e.g. by means of a generalized Tobit model, or the Heckman two-step procedure) and estimate an additional equation for the firms' propensity to innovate.

The results of these econometric studies are largely consistent with each other and provide fresh empirical evidence on the existence of a positive link between innovation input and output, on the one hand, and innovation output and productivity, on the other. These relationships have been found to hold in large CIS-based samples of firms in various European countries (Cainelli et al., 2006; Crespi et al., 2006; Duguet, 2006; Hall and Mairesse, 2006; Lööf and Heshmati, 2006; Parisi et al., 2006; Van Leuwen and Klomp, 2006). A few studies with availability of CIS data for more than one country have also presented comparative exercises (e.g. pooled regressions with data for different economies) that seem to indicate that the estimated relationship between input, output and productivity is quite similar across different countries in Europe (Lööf et al., 2001; Janz et al., 2003; Griffith et al., 2006).

Despite of the merits of this recent approach, it is however important to point out its possible limitations. In our view, two of them are important. The first is that, despite of the conceptual relevance of the distinction between innovation input and output, it is admittedly difficult to empirically estimate the relationship between them in the context of cross-sectional data such as those based on the CIS surveys. The lack of a reasonable time lag between input, output and productivity performance challenges the validity of this type of measurement exercises, which would arguably require a longer time span (or a panel comprising different waves of the CIS survey).

The second possible limitation refers, in our view, to the theoretical foundation of this type of model. This input-output-performance approach is rooted in a linear understanding of the innovative process that, despite of its appeal and analytical power, does not provide a realistic conceptualisation of the relationships and complex feedback mechanisms existing between the innovative strategies of firms, their economic performance, and the sector-specific characteristics of the market in which they operate. Industry-specific factors, be they technological or economic, exert a considerable influence on the innovative strategies, opportunities and constraints faced by enterprises in different markets. The relationship between innovation and productivity, in our view, may have a well distinct nature in different types of markets and industrial sectors. In order to refine our understanding of the innovation-productivity link, we need a theoretical approach that takes into account the sector-specific nature of technological change.

3. Theoretical model and main hypotheses

The model that we make use of is based on the notion of *technological regime*. A technological regime may be defined as the technological environment in which innovative activities take place in each sector of the economy (Nelson and Winter, 1982; Winter, 1984). A set of industry-specific characteristics define such a technological environment, providing opportunities and constraints for firms that seek to undertake innovative active activities. These industry-specific features refer in particular to the following main characteristics (Cohen and Levin, 1989; Malerba and Orsenigo, 1995).¹

Cumulativeness conditions. These define the extent to which technological activities and performance build upon the accumulated stock of knowledge and technical competencies of each firm (Cefis and Orsenigo, 2001).

Level of technological opportunities. Technological opportunities are commonly defined as the likelihood that technological activities and expenditures lead to an innovative output, i.e. the pace and intensity of technological progress (Breschi et al., 2000). Innovative intensity is achieved, in addition to the internal R&D investments of a firm, also by the acquisition of external knowledge from other actors, e.g. expenditures for the acquisition of machinery, software and R&D services from specialized consultants.

External sources of opportunities. A complementary aspect is the ability of firms to recognize, imitate and exploit the pool of advanced knowledge that is available in the economic environment. External sources of opportunities may be used when firms are able to engage in interactions and cooperations with other agents in the innovation system, such as their suppliers, users, competitors, private R&D labs, Universities and other public research institutes.

Appropriability conditions. Firms typically make use of a variety of instruments to protect the results of their innovative activities from imitation. Appropriability means can roughly be distinguished into formal (e.g. patents and trademarks) and informal

¹ For a more extensive discussion of this approach and a comparison with the mainstream view, see Castellacci (2008a).

means (e.g. process secrecy and know-how, and the complexity of the product and related design).

In a nutshell, the main insight of this approach is that the innovative strategies and activities of enterprises greatly vary across sectors because industries differ fundamentally in terms of the properties of their technological regimes. Our theoretical approach is rooted in this recent line of research, and tries to bring it one step further.

The general idea we put forward is that, given that firms in different sectors of the economy face a distinct set of opportunities, constraints and conditions, these industry-specific characteristics play an important role to explain the enterprises' technological and productivity performance.

In particular, in line with the recent work of Castellacci (2007), we argue that the growth of productivity of a firm is related to the characteristics that define the technological regime in which the enterprise operates. More specifically, we may expect the productivity performance of a firm to be related to the cumulativeness of its innovative process, its level of technological opportunity, its ability to exploit external sources of opportunity, and the effectiveness of its appropriability strategy.

Hypothesis 1. The characteristics of technological regimes are important determinants of the productivity growth of firms.

This general hypothesis may be sharpened and refined by looking at two interrelated and more specific aspects. The first is the distinction between the two distinct sources of productivity growth pointed out in the previous section, namely technical progress and efficiency changes. It would be reasonable to think that the characteristics of technological regimes may have different impacts on these two components of TFP growth.

For instance, a high degree of cumulativeness and a high level of technological opportunities (e.g. a strong commitment to internal R&D activities) may be important factors to shift the technological frontier (technical progress), but may turn out to have no significant effect on the ability of a firm to make efficient use of an already existing technology (efficiency change). In short, we put forward the following

Hypothesis 2. The impacts of technological regime-related factors on technical progress are different from the effects on efficiency change.

A second aspect that it is important to look at in order to sharpen our theory is the type of market structure and industrial dynamics that characterize each industry. The empirical literature on technological regimes has previously investigated the relationships between technological regimes and the characteristics of market structure and industrial dynamics in different sectors of the economy. Several recent works in this field have in particular focused on differences in terms of concentration of innovative activity, size of innovative firms, ease of entry in the market, turbulence or stability in the population of innovative firms (Malerba and Orsenigo, 1995 and 1996; Breschi et al., 2000; Van Dijk, 2000).

These studies have shown that the properties of technological regimes may explain the existence of the innovation patterns originally pointed out by Schumpeter (1934 and 1943). The first, the *Schumpeter Mark I*, is characterized by high ease of entry in the market, low concentration of innovative activity, and a turbulent population of new and old innovators with a significant role played by small firms. Creative destruction (Schumpeter, 1934) is the main feature of this regime (also defined ‘entrepreneurial’ or ‘widening’). The second, the *Schumpeter Mark II* pattern, is characterized by high barriers to entry for new innovators, high concentration of innovative activity, and a stable population mainly formed by large and well-established firms. Creative accumulation (Schumpeter, 1943) is the distinctive feature of such a regime, also defined ‘routinized’ or ‘deepening’.

The stylised distinction between Schumpeter Mark I and II and its relationship to the properties of technological regimes suggest a further refinement of our framework. It is reasonable to conceive, we argue, that the relationship between technological regime-related factors and productivity growth that our model explores will be different in the two Schumpeterian patterns of innovation. The reason is that the mechanism that links innovative activities, technical progress and efficiency changes may indeed work differently in distinct types of market structures.

In the Schumpeter Mark II regime, high cumulateness and appropriability conditions create strong technological entry barriers for new innovators. Productivity growth in this type of market is therefore mostly the result of a continuous process of knowledge accumulation by well-established oligopolistic innovators, where the key

sources of growth are thus represented by dynamic economies of scale and the persistence and cumulateness of innovative activities. Incumbents continuously push the technological frontier further, so that it is technical progress that represents the dominant source of productivity dynamics.

In a Schumpeter Mark I pattern, on the other hand, low cumulateness and appropriability conditions tend to facilitate the continuous entry of new innovative firms. In this context, productivity growth is mainly the result of a process of creative destruction in a turbulent market, where new innovators are more productive than the exit firms they replace. In such a competitive market, the ability of a firm to make efficient use of rapidly changing production techniques becomes a crucial factor, and efficiency improvements thus constitute a more relevant mechanism of productivity growth.

Hypothesis 3. The relationship between technological regimes, technical progress and efficiency changes works differently in different Schumpeterian patterns of innovation. In particular:

- **Hypothesis 3a.** Technical progress is greater in the Schumpeter Mark II than in the Schumpeter Mark I pattern.
- **Hypothesis 3b.** Efficiency change is greater in the Schumpeter Mark I than in the Schumpeter Mark II pattern.

4. A decomposition of TFP growth

The first part of our empirical investigation analyses total factor productivity and decomposes its growth by means of data envelopment analysis. The results of this decomposition exercise will then be used in the next section as dependent variable in a regression analysis that studies the link between innovation and productivity performance.

We make use of frontier production function methods to study the dynamics of productivity of Norwegian firms. This first part of the analysis is based on the Tidsserie-base dataset, containing information on value added, labour and capital investments (deflated by means of industry-level indexes) for a large sample of Norwegian enterprises in both manufacturing and service industries for the period 1998-2004. The number of observations in the dataset varies between around 4000 and 6000 firms for each of the years in the time span.

The Malmquist Index model is based on the non-parametric deterministic production frontiers estimated via data envelopment analysis (DEA; Färe et al. 1994). A major advantage of this approach is that it allows decomposing the dynamics of TFP into technical progress and technical efficiency change. The former is associated with changes in the best-practice production frontier, and the latter with other productivity changes, such as learning by doing, improved managerial practices, and change in the efficiency with which a known technology is applied.

A formal presentation of the TFP decomposition model is presented in Appendix 1. The main intuition of the method is the following. For each industry (defined at the 3-digit level) and each year, the DEA methodology constructs the best-practice production frontier and, based on that, it calculates the levels of technical efficiency of each firm, which measures how distant an enterprise is from the best-practice production frontier of its industry. We have carried out this type of estimations for each year of the available time span, and from these estimations it is then possible to calculate the growth rate of TFP (Malmquist index) and of its two components over the period.

Table 1 reports the results of these estimations for the two sub-periods 1998-2001 and 2002-2004, i.e. the dynamics of TFP, and its decomposition into the technical progress and the efficiency change components. The various rows of the table present averages by sector (2-digit level) of firm-level productivity growth. For interpreting

these results, it should be noticed that values greater (lower) than 1 indicate positive (negative) growth of TFP (or of its two components).

Table 1: Decomposition of total factor productivity growth, average by 2-digit industries and for each period

Industries	1998-2001			2002-2004		
	Malmquist TFP Index	Efficiency change	Technical progress	Malmquist TFP Index	Efficiency change	Technical progress

<i>Average</i>	<i>1.0436</i>	<i>0.9242</i>	<i>1.1772</i>	<i>1.1016</i>	<i>0.9319</i>	<i>1.2632</i>

Looking at the Malmquist TFP index, the table indicates that the growth of total factor productivity has been positive for most of the sectors. The country average is significantly higher in the second period (10.16%) than in the first one (around 4.36%). The sectors that have experienced the most rapid pace of TFP growth are quite diverse, and belong to both manufacturing and services and to both high- and medium-low-tech branches of the economy: food and beverages, leather and footwear, basic metals, motor vehicles, other transport equipment, recycling, radio and TV, wholesale trade, air transport and telecommunication. This would suggest that the process of technological transformation has not only played a relevant role for the most technologically advanced branches of the economy, but also for some of the mature sectors that have traditionally constituted a stronghold of the Norwegian industrial system.

Shifting the focus to the two components of TFP growth, the table suggests that the dynamic pattern of productivity has mostly been obtained, in both sub-periods, by means of technical progress rather than through improvements in technical efficiency. On average, the technical progress component has grown by nearly 18% in the first and 26% in the second period. The growth rate has been particularly high for industries such as electrical, radio and TV, furniture, recycling, sea transport, telecommunication, and computing and software. Interestingly, these are industries that have experienced a high pace of technical progress accompanied by a significant decrease (negative growth) of the efficiency change component.

Technical efficiency has on average decreased by nearly 8% in the first period and 7% in the second. Different sectors have however contributed quite differently to the negative average performance of the efficiency change component, and some industries have indeed experienced efficiency increases in at least one of the two sub-periods (e.g. mining and quarrying, food and beverages, textiles, leather and footwear, basic metals, electrical, motor vehicles, other transport equipment, wholesale trade, air transport, telecommunication).

Summing up, our decomposition exercise indicates that in the period 1998-2004: (1) TFP growth has mostly been obtained through technical progress, whereas technical efficiency has on average decreased; (2) behind this aggregate pattern, the performance of different sectors (and of firms in different industries) has been quite diverse. What are the factors that may explain the diverging dynamics followed by technical progress and efficiency, and to what extent can this be accounted for by the charac-

teristics of technological regimes and the related patterns of market structure and industrial dynamics that characterize different sectors?

5. The link between innovation, technical progress and efficiency

In order to answer this question, the second part of our empirical analysis makes use of innovation data and merges them with the TFP data discussed in the previous section. Data on innovative activities are from the *Third* and the *Fourth Community Innovation Survey* for Norway, referring to the 1998-2000 (CIS3) and 2002-2004 (CIS4) periods respectively. CIS data provide information on a large and representative sample of Norwegian enterprises in all manufacturing and service industries. By merging the CIS3, CIS4 and the TFP data previously estimated from the Tidsserie-base dataset, we are left with a two-period cross-sectional sample, containing around 1000 firms in the first (CIS3) and 1650 firms in the second period (CIS4).

5.1 CIS data, indicators and descriptive analysis

We make use of the following indicators, all of which are available in both periods and have identical definition in the two waves of the innovation survey.

Firm-specific factors

- **Employment (log):** Number of employees (log), a standard measure of firm size.
- **Group:** a dummy variable indicating whether a firm belongs to a group.
- **Product life:** a variable indicating the average length of the firm's product cycle.
- **Export intensity:** export divided by total turnover, in 2001 and 2004.
- **Market location:** a categorical variable that indicates whether a firm sells its products and services in local, national, European or other international markets.
- **TFP level:** level of total factor productivity, average of the period.

Technological regimes factors

- **Cumulativeness:** Continuous R&D: a dummy variable that indicates whether a firm is *continuously* engaged in R&D activities (rather than being an occasional innovator).
- **Level of technological opportunities:** We make use of three indicators to measure the intensity of a firm internal R&D effort as well as its acquisition of external R&D and other types of specialized knowledge. (1) R&D intensity (internal R&D expenditures, share of total turnover); (2) Other external knowledge (acquisition of software and other external knowledge, share of total innovation costs); (3) R&D purchase (expenditures for the purchase of R&D, share of total innovation costs).
- **External sources of opportunities:** a set of dummy variables indicating whether a firm regards the following actors as important sources of information for their technological activities: other sources in the same firm (S-Internal); other firms in the same group (S-Group); suppliers; users; competitors; consultants; private R&D labs; Universities; public research institutes.
- **Appropriability conditions:** Two dummy variables that indicate whether each firm has made use of the following (formal and informal) appropriability modes: trademark; patent; secrecy; complex design.

Other innovation-related variables

- **Effects of innovation:** Three dummy variables indicating whether each firm states that technological change has led to the following effects and results: increasing market shares or entering new markets (E-Market orientation); increasing the productive capacity (E-Productive capacity); decreasing the labour costs (E-Labour costs).

- **Hampering factors:** A set of dummy variables indicating whether a firm considers the following factors as important obstacles to its innovative activities: high costs (H-Costs); lack of qualified personnel (H-Personnel); lack of information on technology (H-TechInfo); lack of other information (H-OtherInfo).

Table 2 presents some descriptive evidence on the variables measuring firm-specific factors. The table reports the mean and standard deviation of these variables for both the CIS3 and the CIS4 dataset. As customary in this type of analysis based on CIS data, the table reports these descriptive statistics separately for the innovative and non-innovative sample (the distinction is applied by means of an “innovator dummy” variable that takes value 0 if a firm has had no innovation costs at all, and 1 otherwise).

The differences between the innovative and non-innovative samples are evident in both periods, and their statistical significance is shown through the results of a non-parametric Mann-Whitney U test. In particular, firms in the innovative sample are characterized by higher TFP levels, greater firm size and group structure, shorter product life cycle, higher export intensity and greater relevance of international commercialisation markets.

This descriptive evidence, which is consistent with what previous studies based on CIS firm-level data have found for other countries, provides one first relevant indication for the econometric study that we intend to undertake. Given the significant differences between innovative and non-innovative firms in our sample, selection-bias may occur in our econometric estimations. This is due to the fact that in the CIS questionnaire non-innovative enterprises do not answer the questions on innovative activities, strategies and performance, and are therefore excluded from the regressions studying the links between innovation and productivity growth. For this reason, in order to take into account this type of sample selection problem, the estimations that we will present make use of a Heckman two-step procedure, as standard in the CDM econometric approach (see section 2).

Table 2: Descriptive statistics: Characteristics of innovative and non-innovative samples, 1998-2000 (CIS3) and 2002-2004 (CIS4)

	1998-2000 (CIS3)					2002-2004 (CIS4)

^a Mann-Whitney U test for the difference between the two samples. The values reported in the column are the z scores from the test. Positive (negative) z scores indicate that the variable is smaller (greater) for innovators than for non-innovators. Significance levels: *** 1%; ** 5%; * 10%.

Next, we present some descriptive evidence on the differences between the characteristics of firms in distinct Schumpeterian regimes. Table 3 reports the mean and the coefficient of variation (CV) of firms in the two distinct types of market structure and industrial dynamics that are typically labelled Schumpeter Mark I and Schumpeter Mark II.

The distinction between Schumpeter Mark I and II regimes, while clear from a conceptual point of view, is not easy to apply in empirical analyses, given that there exist no well-established criteria to decide whether each sector of the standard industrial classification belongs to one or the other regime. Previous empirical studies in the field, however, have carefully analysed this aspect and provided a list of industries belonging to each Schumpeterian regime (Malerba and Orsenigo, 1995, p. 58; Breschi et al., 2000, p. 400; Van Dijk, 2000, pp. 192-194; Marsili and Verspagen, 2002, pp. 814-815; Castellacci, 2008b). In addition, the recent paper by Castellacci et al. (2008) has investigated this issue by means of a factor and cluster analysis exercise applied to a large number of indicators on market structure and industrial dynamics of Norwegian firms in all manufacturing and service industries. Our division of sectors into Schumpeter Mark I and II regimes follows therefore these previous empirical works.² For both periods, table 3 reports the results of a non-parametric Mann-Whitney U test that investigates the differences between firms in the two Schumpeterian regimes. The test confirms that enterprises differ significantly when they operate in distinct market and industrial dynamics conditions. Firms in the Schumpeter Mark II pattern have greater R&D intensity and cumulativeness of technological change, and they also tend to be larger and more oriented to international markets.

While this confirms the basic characteristics of the Schumpeter Mark I and II distinction, a more novel indication is provided by the analysis of their differences with respect to the variables measuring productivity dynamics. The technical progress component of TFP growth proves to be significantly more dynamic for firms in the Schumpeter Mark II regime, whereas the efficiency change component is higher for enterprises in the Schumpeter Mark I type of markets. Considering the joint effects of

² The list of sectors in the two Schumpeterian regimes is the following. *Schumpeter Mark I sectors*: mining; textiles; wearing; leather and footwear; wood and related products; printing and publishing; non-metallic mineral products; fabricated metals; machinery and equipment; electrical; radio and TV; medical and optical; other transport equipment; furniture; recycling; construction; wholesale trade; land transport; auxiliary transport services; research and development. *Schumpeter Mark II industries*: motor vehicles; food and beverages; pulp and paper; basic metals; sea transport; air transport; telecommunication; computing and software; other business services.

these two components of productivity, the growth of TFP has been slightly larger for firms in the Schumpeter Mark I than in the Schumpeter Mark II pattern (3.5% against 0.7%, and 6.4% versus 3.9%).

This finding is, in our view, quite interesting, and it provides empirical support for the third hypothesis that we have previously put forward (see section 3, hypotheses 3a and 3b). Our interpretation of this result is that the mechanism of productivity growth differs in the two Schumpeterian regimes. While Schumpeter Mark II markets are characterized by an oligopolistic structure where large incumbent innovators continuously and cumulatively push the technological frontier further (technical progress), firms in Schumpeter Mark I industries must devote a significant effort to make an efficient use of already available techniques (efficiency change), which is a crucial requirement to survive in competitive and turbulent markets.

Table 3: Descriptive statistics: A comparison of Schumpeter Mark I and Schumpeter Mark II sectors, 1998-2000 (CIS3) and 2002-2004 (CIS4)

5.2 Model specification and estimation results

In the analysis of the links between innovation and productivity growth, we employ a model specification and estimation strategy able to take into account the two issues highlighted by the descriptive evidence presented in section 5.1. The first, the possible problem of selection-bias, is tackled by making use of the Heckman two-step methodology. The second, the differences between firms in the Schumpeter Mark I and Mark II patterns, is taken into account by estimating a piecewise linear regression of the model (i.e. by including constant and slope dummies to control for differences among the two regimes).

The Heckman two-step estimation method corrects for the possible presence of selection-bias that is caused by the exclusion of non-innovative firms (which, as previously shown, are significantly different from enterprises in the innovative sample). The first step of the procedure estimates a selection equation, which investigates the factors explaining the probability that a firm is an innovator. The second step studies the links between innovation and productivity growth, including, among the other regressors, also the inverse Mills ratio that corrects for the sample selection bias.

The dependent variable in the selection equation is an “innovator dummy” variable (taking value 0 if a firm has had no innovation costs at all, and 1 otherwise). The explanatory factors are firm-specific indicators that are typically used in several recent CDM applied works (Hall and Mairesse, 2006). Nearly all of these factors turn out to be significant in the first-step regression presented in the tables. The probability of being an innovator increases with firm size, its group structure, its international market orientation, and it decreases with the length of the product life (suggesting that the shorter the life cycle the greater the need to invest in innovative activities). Besides, the probability of being an innovator is positively related to the four dummy variables measuring different types of hampering factors in the enterprise innovative process, i.e. high costs, lack of qualified personnel, lack of technical information or other types of information. The positive sign of this estimated relationship is not surprising and it is consistent with previous works, suggesting that innovative firms have a greater awareness of the main factors that hamper their innovative activities.

The second-step equation studies the relationships between innovation and the two distinct components of TFP growth. We therefore estimate two distinct (second-step) equations. The first relates the growth of technical progress to the set of explanatory variables that have been presented in section 5.1, namely the characteristics of tech-

nological regimes and a set of other firm-specific factors. The second equation makes use of the same set of explanatory variables to explore their impact on the growth of efficiency.

For each of these two equations, we estimate three different specifications: the first includes dummies for all manufacturing and service industries; the second includes, instead of the whole set of industry dummies, a constant dummy for firms in Schumpeter Mark II sectors; the third specification includes, in addition, a set of slope dummies for enterprises in Schumpeter Mark II sectors.³ All the regressions also include a time dummy that controls for differences between the two sub-periods. Results for the determinants of technical progress are presented in table 4, whereas those for efficiency change are reported in table 5.

Table 4 provides basic support for our technological regime model, and indicates that the statistical precision of many of the estimated coefficients is higher in the versions of the model that control for differences between the two Schumpeterian patterns of innovation (reported in the last two columns). Among the firm-specific factors, the level of TFP turns out to have a high negative estimated coefficient, and the inverse relationship between efficiency level and technical progress appears to be even more pronounced in the Schumpeter Mark II regime. Besides, technical progress is positively related to firm size, the ‘part of a group’ dummy variable (in the Schumpeter Mark II), and the international location of markets (only in the Schumpeter Mark I). It is instead negatively related to the length of the product life, which has a much stronger effect in the Schumpeter Mark II than in the Mark I pattern.

Shifting the focus to the technological regime explanatory variables, we observe that the coefficient of the cumulativeness dummy variable is positive, as expected, but when we control for differences between the Schumpeter Mark I and II, it turns out to be negative for the latter. Regarding the variables measuring the levels of technological opportunity, the R&D intensity turns out to be positive, and the variable measuring the acquisition of software and other external knowledge has a quite strong posi-

³ In the piecewise linear regression version of the model, slope dummies have initially been included for all of the explanatory variables. However, in the final specification presented here the slope dummies have been retained only if their inclusion contributes to improve the explanatory power of the model. When a slope dummy is included in the regression, the estimated coefficient for the Schumpeter Mark II regime is the algebraic sum of the overall estimated coefficient of the regressor and the one of the corresponding slope dummy. On the other hand, if the slope dummy is not included, the estimated coefficient is the same for the two regimes.

tive effect on technical progress. Among the external sources of opportunity dummy variables, only internal sources and competitors on the same market have a significant estimated coefficient (in at least some of the regressions). The dummies measuring formal and informal appropriability means are instead not significant at conventional levels.

The last group of regressors measure other aspects of the innovative process, such as hampering factors and effects of innovation. These variables provide some additional interesting indications on the nature and performance of innovative activities of Norwegian firms. The lack of qualified personnel is negatively related to productivity growth, while the lack of technical information is negatively (positively) related to it in the Schumpeter Mark II (Mark I) regime. On the other hand, the variables measuring the firm ability to increase market shares and entering new markets and the expansion of its productive capacity have both a positive effect on technical progress.

Last, the time dummy confirms that technical progress has been stronger in the second than in the first period (see section 4, table 1), while the Schumpeter Mark II constant dummy indicates that technical progress has been significantly more rapid for firms in the Schumpeter Mark II than in the Schumpeter Mark I. This provides further empirical support for the third hypothesis put forward in section 3 (see hypothesis 3a).

Table 5 presents the results of the estimations exploring the determinants of the efficiency change component of TFP growth. First, looking at the set of firm-specific indicators, efficiency improvements are positively related to firm size, the ‘part of a group’ dummy variable, and the international market orientation of the enterprise. The main difference as compared to the results in table 4 refers to the level of TFP. This variable turns out to be positively related to the dynamics of technical efficiency. Interestingly, this pattern is just the opposite as the one found for the technical progress component. One possible interpretation of this finding is that the dynamics of technical efficiency, representing changes such as learning by doing and improvements in managerial practices, grows in a cumulative way because it builds upon existing levels of knowledge stocks, human capital and the absorptive capacity of a firm. On the other hand, technical progress requires a continuous and intensive effort to introduce brand new processes, products and services, and this active search for disruptive new technologies may possibly displace resources and decrease the efficiency of a firm in the short run.

Secondly, some of the effects of the technological regime related variables do also differ. The purchase of R&D from external specialized providers seems to be an important channel to improve technical efficiency, whereas the internal R&D and cumulativeness variables are not significant in the two model specifications that control for differences between the Schumpeterian regimes. Among the external sources of opportunities, only internal sources and consultants turn out to be relevant channels to achieve efficiency improvements.

Thirdly, the group of variables measuring other aspects of the innovative process also shows some interesting differences *vis-à-vis* the determinants of technical progress. The hampering factors indicators are in fact both positively related to efficiency change, a possible interpretation being that when there exist significant obstacles to undertake innovative activities, a more convenient strategy for the firm is instead to devote resources to the improvements of its technical efficiency. As for the effects of innovation variables, efficiency growth is positively related to the market orientation of the firm and to its ability to save on labour costs. It is also negatively linked to increases in the firm’s production capacity, given that a higher productive capacity makes it more difficult for an enterprise to achieve a full utilization of it in the short run, thus lowering technical efficiency.

Finally, looking at the Schumpeter Mark II constant dummy, this indicates that efficiency change has been significantly more rapid for firms in the Schumpeter Mark I than in the Schumpeter Mark II. This provides further support for the third hypothesis put forward in section 3 (see hypothesis 3b).

6. Conclusions

The paper has analysed the dynamics of productivity of Norwegian firms in the period 1998-2004, and it has investigated the relationships between TFP growth and technological regimes. The empirical analysis has proceeded in two steps. First, we have employed data envelopment analysis in order to decompose the growth of TFP into two distinct components, technical progress and efficiency change. Then, we have explored the determinants of these two components by estimating a model that links technological regime-related factors and a set of other firm-specific characteristics to the productivity performance of Norwegian enterprises.

Our main results can be summarized as follows. First, the productivity decomposition exercise indicates that in the period 1998-2004 TFP growth has mostly been obtained through technical progress, whereas technical efficiency has on average decreased.

The technological regime type of model that we have put forward to investigate the determinants of these two distinct components appears to perform reasonably well in the econometric estimations, and provides basic support for the first of our theoretical hypotheses (see section 3, hypothesis 1).

Specifically, both components of productivity growth are significantly related to the level of technological opportunities (as measured by the acquisition of external knowledge), other sources of opportunities within the same firm, the ability of the enterprise to increase market shares and entering new markets, as well as a set of other firm-specific characteristics such as size, export orientation and the average length of the product cycle.

Secondly, the econometric results also indicate that some of the explanatory variables in the model have different effects on the two distinct components of productivity growth. This provides support for the second hypothesis put forward by our theoretical framework (see section 3, hypothesis 2).

In particular, internal R&D efforts and the cumulateness of R&D activities are important factors for the dynamics of technical progress but not for efficiency change. Among the external sources of opportunity, competitors on the same market are important for technical progress, whereas interacting with the consultants seems to constitute a more relevant factor to achieve efficiency improvements. Increases in the productive capacity of the firm are, quite obviously, positively related to technical progress but negatively linked to the efficiency component. Last, the level of TFP

shows a strong negative (positive) relationship with technical progress (efficiency change), thus suggesting a possible trade-off in the short-run between the efforts devoted to the introduction of new technologies and the achievement of high efficiency in the utilization of existing techniques.

Thirdly, the empirical results also provide support for the idea that the relationships between technological regimes, technical progress and efficiency changes work differently in different Schumpeterian patterns of innovation (see section 3, hypothesis 3). In the piecewise linear regression version of our econometric model, many of the explanatory variables turn out to have different estimated coefficients in the Schumpeter Mark I and in the Schumpeter Mark II regimes. This is particularly the case in the technical progress equation, where several regressors significantly differ among the regimes (e.g. cumulateness, group structure, length of the product life, market location, lack of technological information as a main hampering factor).

These results also indicate that the technical progress component of TFP growth has proved to be significantly more dynamic for firms in the Schumpeter Mark II regime (hypothesis 3a), whereas the efficiency change component has been higher for enterprises in the Schumpeter Mark I type of markets (hypothesis 3b).

Our interpretation of this result is that the mechanism of productivity growth differs in the two Schumpeterian regimes. While Schumpeter Mark II markets are characterized by an oligopolistic structure where large incumbent innovators continuously and cumulatively push the technological frontier further (technical progress), firms in Schumpeter Mark I industries must devote a significant effort to make an efficient use of already available techniques (efficiency change), which is a crucial requirement to survive in competitive and turbulent markets.

Appendix 1: The TFP decomposition method

We report here a formal presentation of the TFP decomposition method based on data envelopment analysis, whose results have been presented in section 4 and later used in the regression analysis in section 5. Following Färe et al. (1994) to define the output-based Malmquist index of productivity change, we assume that, for each time period $t=1, \dots, T$, the production technology \mathbf{S}^t models the transformation of inputs, $\mathbf{x}^t \in \mathbf{R}_+^N$, into outputs, $\mathbf{y}^t \in \mathbf{R}_+^M$, as follows:

$$\mathbf{S}^t = \{(\mathbf{x}^t, \mathbf{y}^t): \mathbf{x}^t \text{ can produce } \mathbf{y}^t\}. \quad (1)$$

The output distance function is defined at t as:

$$\begin{aligned} D_o^t(\mathbf{x}^t, \mathbf{y}^t) &= \inf\{\theta: (\mathbf{x}^t, \mathbf{y}^t/\theta) \in \mathbf{S}^t\}. \\ &= (\sup\{\theta: (\mathbf{x}^t, \theta\mathbf{y}^t) \in \mathbf{S}^t\})^{-1}. \end{aligned} \quad (2)$$

Note that $D_o^t(\mathbf{x}^t, \mathbf{y}^t) \leq 1$ if and only if $(\mathbf{x}^t, \mathbf{y}^t) \in \mathbf{S}^t$. In addition, $D_o^t(\mathbf{x}^t, \mathbf{y}^t) = 1$ if and only if $(\mathbf{x}^t, \mathbf{y}^t)$ is on the boundary or frontier of the technology. According to Farrell (1957), this occurs when production is technically efficient. In the case of a single input and one output, under constant returns to scale, maximum feasible output is achieved when average productivity, y/x , is maximized. In our empirical work, that maximum is the best practice or highest productivity observed in our sample and is determined using DEA techniques.

To define the Malmquist index, we characterize a distance function with respect to two different time periods as follows:

$$D_o^t(\mathbf{x}^{t+1}, \mathbf{y}^{t+1}) = \inf\{\theta: (\mathbf{x}^{t+1}, \mathbf{y}^{t+1}/\theta) \in \mathbf{S}^t\}. \quad (3)$$

This function measures the maximal proportional change in outputs required to make $(\mathbf{x}^{t+1}, \mathbf{y}^{t+1})$ feasible in relation to the reference or benchmark technology at t . Similarly, a distance function that measures the maximal proportional change in output required to make $(\mathbf{x}^t, \mathbf{y}^t)$ feasible in relation to the technology at $t+1$, denoted $D_o^{t+1}(\mathbf{x}^t, \mathbf{y}^t)$ may be defined. In order to avoid choosing an arbitrary benchmark between t and $t+1$, we specify the output-based Malmquist productivity change index as the geometric mean of two Malmquist productivity indexes, one with technology at t and the other at $t+1$ as benchmarks, as follows:

$$M_o(\mathbf{x}^{t+1}, \mathbf{y}^{t+1}, \mathbf{x}^t, \mathbf{y}^t) = \left[\left(\frac{D_o^t(\mathbf{x}^{t+1}, \mathbf{y}^{t+1})}{D_o^t(\mathbf{x}^t, \mathbf{y}^t)} \right) \left(\frac{D_o^{t+1}(\mathbf{x}^{t+1}, \mathbf{y}^{t+1})}{D_o^{t+1}(\mathbf{x}^t, \mathbf{y}^t)} \right) \right]^{1/2}. \quad (4)$$

In all definitions concerning Malmquist indexes, we assume constant returns to scale for the technology as suggested in Färe and Grosskopf (1996). The Malmquist productivity index in (4) can be disaggregated multiplicatively into two component measures:

$$\text{EFFCH} = \frac{D_o^{t+1}(\mathbf{x}^{t+1}, \mathbf{y}^{t+1})}{D_o^t(\mathbf{x}^t, \mathbf{y}^t)}, \quad (5)$$

and

$$\text{TECH} = \left(\frac{D_o^t(\mathbf{x}^{t+1}, \mathbf{y}^{t+1})}{D_o^{t+1}(\mathbf{x}^{t+1}, \mathbf{y}^{t+1})} \frac{D_o^t(\mathbf{x}^t, \mathbf{y}^t)}{D_o^{t+1}(\mathbf{x}^t, \mathbf{y}^t)} \right)^{1/2}, \quad (6)$$

where the expression in (5) measures the change in efficiency between periods t and $t+1$, which we denote *efficiency change*. Expression (6) captures shifts in the frontier technology, which we denote to be the *technical progress* component. Values less than one in both cases signify deterioration in productivity.

We calculate the Malmquist productivity index using non-parametric programming techniques. We assume that there are $k=1, \dots, K$ enterprises using $n=1, \dots, N$ inputs $x_n^{k,t}$ at each time period $t=1, \dots, T$. These inputs are used to produce $m=1, \dots, M$ outputs $y_m^{k,t}$. Each observation of inputs and outputs is strictly positive and we assume that the number of observations remains constant over all years, although this is not always the case with our data. The reference, or frontier, technology in period t is constructed from the data as:

$$\begin{aligned} \mathbf{S}^t = \{(\mathbf{x}^t, \mathbf{y}^t) : y_m^t &\leq \sum_{k=1}^K z^{k,t} y_m^{k,t} \quad m = 1, \dots, M, \\ \sum_k z^{k,t} x_n^{k,t} &\leq x_n^t \quad n = 1, \dots, N, \text{ and} \\ z^{k,t} &\geq 0 \quad k = 1, \dots, K\}. \end{aligned} \quad (7)$$

It exhibits constant returns to scale and strong disposability of inputs and outputs (Färe and Grosskopf, 1996).

To calculate the productivity of enterprise k' between t and $t+1$, we solve four different linear-programming problems: $D_o^t(\mathbf{x}^t, \mathbf{y}^t)$, $D_o^{t+1}(\mathbf{x}^t, \mathbf{y}^t)$, $D_o^t(\mathbf{x}^{t+1}, \mathbf{y}^{t+1})$, and $D_o^{t+1}(\mathbf{x}^{t+1}, \mathbf{y}^{t+1})$. For each $k'=1, \dots, K$,

$$\left(D_o^t(\mathbf{x}^{k',t}, \mathbf{y}^{k',t})\right)^{-1} = \max \theta^{k'}$$

subject to :

$$\theta^{k'} y_m^{k',t} \leq \sum_{k=1}^K z^{k,t} y_m^{k,t} \quad m = 1, \dots, M, \quad (8)$$

$$\sum_{k=1}^K z^{k,t} x_n^{k,t} \leq x_n^{k',t} \quad n = 1, \dots, N, \quad \text{and}$$

$$z^{k,t} \geq 0 \quad k = 1, \dots, K.$$

This linear programming problem is the basis for DEA and the distance function estimates are referred to as DEA efficiency estimates in the literature.
